- Mild conditions guarantee the convergence of the algorithm but not the convergence rate!

Lecture 9: Brief Reminder

We are learning about the MCMC algorithm:

- What it is and why does it work
- Elements of the algorithm:
 - ▶ Target distribution $\pi(x)$ - Problem determined
 - ▶ Proposal distribution $Q(y|x)$ - Chosen by us
 - ▶ Acceptance probability $\alpha(y|x)$ - Computed s.t. the detailed balance holds
- Mild conditions guarantee the convergence of the algorithm but not the convergence rate!
- We have looked at two special proposal densities:
 - ▶ The independence proposal $Q(y|x) = Q(y)$
 - ▶ The RW proposal $Q(y|x) = Q(x|y)$
- Importance of the tuning parameter

Review: Special cases Metropolis-Hastings

- **Metropolis algorithm:** The proposal density is symmetric around the current value, that means

$$Q(x_{i-1}|y) = Q(y|x_{i-1}).$$

Hence,

$$\alpha = \min \left(1, \frac{\pi(y)}{\pi(x_{i-1})} \times \frac{Q(x_{i-1}|y)}{Q(y|x_{i-1})} \right) = \min \left(1, \frac{\pi(y)}{\pi(x_{i-1})} \right)$$

Acceptance rates should be between 20% and 50%.

- **Independence sampler:** The proposal distribution does not depend on the current value x_{i-1}

$$Q(x|x_{i-1}) = Q(x).$$

$Q(x)$ is an approximation to $\pi(x) \Rightarrow$ acceptance rate should be high.

MCMC and iterative conditioning

The MH-algorithm can be applied iteratively on the different elements of a stochastic vector \mathbf{x} conditioning on all other elements.

To be concrete, one uses

- a proposal kernel $Q(y^j | \mathbf{x}_{i-1}^j, \mathbf{x}_{i-1}^{-j})$, $j = 1, \dots, p$.
- with acceptance probability

$$\alpha = \min \left(1, \frac{\pi(y^j | \mathbf{x}_{i-1}^{-j})}{\pi(\mathbf{x}_{i-1}^j | \mathbf{x}_{i-1}^{-j})} \times \frac{Q(\mathbf{x}_{i-1}^j | y^j, \mathbf{x}_{i-1}^{-j})}{Q(y^j | \mathbf{x}_{i-1}^j, \mathbf{x}_{i-1}^{-j})} \right)$$

This algorithm **converges to the stationary distribution with density $\pi(\mathbf{x})$** , as long as all components are arbitrary often updated.

Conditional densities

The **full conditional densities** $\pi(x^j | \mathbf{x}^{-j})$, $j = 1, \dots, p$, and the joint density $\pi(\mathbf{x})$ are related as follows:

$$\pi(x^j | \mathbf{x}^{-j}) = \frac{\pi(\mathbf{x})}{\pi(\mathbf{x}^{-j})} \propto \pi(\mathbf{x})$$

Thus, the (non-normalised) conditional densities of $x^j | \mathbf{x}^{-j}$ can be directly derived from $\pi(\mathbf{x})$ by **omitting all multiplicative factors, that do not depend on x^j** .

Gibbs sampling

Idea: **Sequentially sampling** from univariate conditional distributions (which are often available in closed form).

1. Select starting values \mathbf{x}_0 and set $i = 0$.

2. Repeatedly:

Sample $x_{i+1}^1 | \cdot \sim \pi(x^1 | x_i^2, \dots, x_i^p)$

Sample $x_{i+1}^2 | \cdot \sim \pi(x^2 | x_{i+1}^1, x_i^3, \dots, x_i^p)$

\vdots

Sample $x_{i+1}^{p-1} | \cdot \sim \pi(x^{p-1} | x_{i+1}^1, x_{i+1}^2, \dots, x_{i+1}^{p-2}, x_i^p)$

Sample $x_{i+1}^p | \cdot \sim \pi(x^p | x_{i+1}^1, \dots, x_{i+1}^{p-1})$

where $|\cdot$ denotes conditioning on the most recent updates of all other elements of \mathbf{x} .

3. Increment i and go to step 2.

Gibbs sampling

The Gibbs sampler is a special case of the MH-algorithm.

The acceptance probability is always 1

Plan for today

- Gibbs sampling
- Blocking strategies
- Convergence diagnostic

Example: Simple linear regression

Let

$$Y_i = a + bx_i + e_i, \quad e_i \sim \mathcal{N}(0, 1/\tau), \quad i = 1, \dots, n$$

and

$$a \sim \mathcal{N}(0, 1/\tau_a)$$

$$b \sim \mathcal{N}(0, 1/\tau_b)$$

$$\tau \sim \text{Gamma}(\alpha, \beta)$$

we are interested in the posterior:

$$\pi(a, b, \tau | y)$$

(See notes, show R-code `demo_linear_regression.R`)

Remarks on Gibbs sampling

- High dimensional updates of \mathbf{x} can be boiled down to scalar updates.
- **Visiting schedule:** Various approaches exist (and can be justified) to ordering the variables in the sampling loop. One approach is random sweeps: variables are chosen at random to resample.
- Gibbs sampling assumes that it is easy to sample from the full-conditional distribution. This is sometimes not so easy. Alternatively, a Metropolis-Hastings proposal can be used for the j -th component, i.e. **Metropolis-within-Gibbs** \Rightarrow **Hybrid Gibbs sampler**.

Remarks on Gibbs sampling

- **Blocking or grouping** is possible, that means not all elements of \mathbf{x} are treated individually. Might be useful when elements of \mathbf{x} are correlated.
- **Care must be taken when improper prior are used**, which may lead to an **improper posterior distribution**. Impropriety implies that there does not exist a joint density to which the full-conditional distributions correspond.

Hobert, J. P. and Casella, G. (1996), JASA, 91: 1461–1473.

Example : Conjugate gamma-Poisson hierarchical model

Example from George et al. (1993) regarding the analysis of 10 power plants.

- y_i number of failures of pump i
- t_i length of operation time of pump i (in kilo hours)

Model:

$$y_i \mid \lambda_i \sim \text{Po}(\lambda_i t_i)$$

Conjugate prior for λ_i :

$$\lambda_i \mid \alpha, \beta \sim \text{G}(\alpha, \beta)$$

Hyper-prior on α and β :

$$\alpha \sim \text{Exp}(1.0)$$

$$\beta \sim \text{G}(0.1, 10.0)$$

Conjugate gamma-Poisson hierarchical model (II)

The posterior of the 12 parameters $(\alpha, \beta, \lambda_1, \dots, \lambda_{10})$ given y_1, \dots, y_{10} is proportional to

$$\begin{aligned} \pi(\alpha, \beta, \lambda_1, \dots, \lambda_{10} \mid y_1, \dots, y_{10}) &\propto \pi(\alpha)\pi(\beta) \prod_{i=1}^{10} [\pi(\lambda_i \mid \alpha, \beta)\pi(y_i \mid \lambda_i)] \\ &\propto e^{-\alpha} \beta^{0.1-1} e^{-10\beta} \left\{ \prod_{i=1}^{10} \exp(-\lambda_i t_i) \lambda_i^{y_i} \right\} \left\{ \prod_{i=1}^{10} \exp(-\beta \lambda_i) \lambda_i^{\alpha-1} \right\} \left[\frac{\beta^\alpha}{\Gamma(\alpha)} \right]^{10}. \end{aligned}$$

This posterior is **not of closed form**.

Conjugate gamma-Poisson hierarchical model (II)

The posterior of the 12 parameters $(\alpha, \beta, \lambda_1, \dots, \lambda_{10})$ given y_1, \dots, y_{10} is proportional to

$$\begin{aligned} \pi(\alpha, \beta, \lambda_1, \dots, \lambda_{10} \mid y_1, \dots, y_{10}) &\propto \pi(\alpha)\pi(\beta) \prod_{i=1}^{10} [\pi(\lambda_i \mid \alpha, \beta)\pi(y_i \mid \lambda_i)] \\ &\propto e^{-\alpha} \beta^{0.1-1} e^{-10\beta} \left\{ \prod_{i=1}^{10} \exp(-\lambda_i t_i) \lambda_i^{y_i} \right\} \left\{ \prod_{i=1}^{10} \exp(-\beta \lambda_i) \lambda_i^{\alpha-1} \right\} \left[\frac{\beta^\alpha}{\Gamma(\alpha)} \right]^{10}. \end{aligned}$$

This posterior is **not of closed form**.

Work out the full conditional distributions yourself!

Update scheme for gamma-Poisson hierarchical model

For each iteration i

- For $k = 1, \dots, 10$
 - ▶ Simulate new value $\lambda_k \sim \text{Gamma}(y_i + \alpha, t_i + \beta)$ Gibbs step
- Simulate new value $\beta \sim \text{Gamma}(10\alpha + 0.1, \sum \lambda_k + 1)$ Gibbs step
- Propose new value $\alpha_{new} \sim \mathcal{N}(\alpha_{i-1}, \tau)$ MH step
- Compute acceptance probability

$$a = \min \left\{ 1, \frac{\pi(\alpha_{new} | \dots)}{\pi(\alpha_{old} | \dots)} \right\}$$

- if $u < a$
 - ▶ set $\alpha_i = \alpha_{new}$
- else
 - ▶ set $\alpha_i = \alpha_{old}$

Blocking Strategies

Blocking (ie simulating some variables together) might improve the algorithm especially when variables are correlated.

Example: Korsbetningen

In the year of our Lord 1361, on the third day after S:t Jacob, the Goth fell outside the gates of Visby at the hands of the Danish. They are buried here. Pray for them.

- Archeological excavation found 493 femurs, 256 right and 237 left
- At least 256 person were buried here....but how many more??

A simple model

Let x_1 and x_2 be the number of left and right femurs found.

Assume x_1 and x_2 to be two independent observations from a $\text{Bin}(N, \phi)$ distribution.

With

- N total number of people buried
- ϕ probability of finding a femur, left or right

The unknown parameter vector is $\theta = (N, \phi)$. Assume a $\text{Beta}(a, b)$ prior for ϕ , and a $\text{Unif}(256, 2500)$ prior for N .

Updating schemes

Single site update

- Simulate new $\phi \sim \text{Beta}(\cdot, \cdot)$
(Gibbs step)
- Propose $N_{new} \sim \text{Unif}(N_{old} - d, N_{old} + d)$
- Compute

$$\alpha = \min \left\{ 1, \frac{\pi(N_{new} | \dots)}{\pi(N_{old} | \dots)} \right\}$$

- Accept or reject the new value for N

(Show R-code Vikings.R)

Block update

- Propose a new value N_{new} for N from
 $\text{Unif}(N_{old} - d, N_{old} + d)$
- Propose a new value ϕ_{new} for ϕ from

$$\text{Beta}(\alpha + x_1 + x + 2, \beta + 2N_{new} - x_1 - x_2)$$

- Compute α
- Accept or reject N_{new} and ϕ_{new} simultaneously

Implementation and convergence diagnostics

Source: http://i.telegraph.co.uk/multimedia/archive/02365/coding_alamy_2365972b.jpg

Convergence

- If well constructed, the Markov chain is guaranteed to have the posterior as limiting distribution.
- However, this does not tell you how long you have to run the MCMC algorithm til convergence.
 - ▶ The initial position may have a big influence.
 - ▶ The proposal distribution may lead to low acceptance rates.
 - ▶ The chain may get caught in a local maximum of the likelihood surface.
- We say the **Markov chain mixes well** if it can
 - ▶ reach the posterior quickly, and
 - ▶ moves quickly around the posterior modes.

Convergence diagnostics

Valid inferences from sequences of MCMC outputs are based on the assumption that the outputs are from the desired target distribution.

- There is no overall minimum number of samples to ensure approximation.
- Consequently methods for testing convergence, known as convergence diagnostics, have to be applied.
- However it has to emphasised that **these diagnostics do not guarantee convergence.**

Trace plots

An initial possibility for deciding if a MCMC output does not converge to the desired posterior distributions is to look at the **sample trace for each variable**.

- If our chain is taking a long time to move around the parameter space, then it will take longer to converge.

Trace plots

An initial possibility for deciding if a MCMC output does not converge to the desired posterior distributions is to look at the **sample trace for each variable**.

- If our chain is taking a long time to move around the parameter space, then it will take longer to converge.
- If the samples form a **homogeneous band** (no wave movements or other rare fluctuations), convergence might be indicated.

Trace plots

An initial possibility for deciding if a MCMC output does not converge to the desired posterior distributions is to look at the **sample trace for each variable**.

- If our chain is taking a long time to move around the parameter space, then it will take longer to converge.
- If the samples form a **homogeneous band** (no wave movements or other rare fluctuations), convergence might be indicated.
- Vastly different values at the beginning of the trace indicate **burn-in iterations**, which should be discarded.

Burn-in

In practice, one waits until the Markov chain is converged. Let K denote the **burn-in period**. Then the realisations $\mathbf{x}_{K+1}, \mathbf{x}_{K+2}, \dots, \mathbf{x}_{K+N}$ are used to estimate characteristics of the target distribution.

The empirical determination of K is difficult. Often it is determined based on the **trace plot** of the Markov chain.

Output analysis

Standard starting point to evaluate convergence:

- Look at the trace plot for each variable
- consider different scalar function of x
- may run different Markov chain with different (extreme) starting values

Example: Korsbetningen

Single site update, two chains with different starting values

Example: Korsbetningen

Block update, two chains with different starting values

Example: Korsbetningen

Single site update, two chains with different starting values.

Estimate of the mean

Example: Korsbetningen

Block update, two chains with different starting values.

Estimate of the mean

Convergence Diagnostic

With a fixed cpu-time should we:

- use all time in one long Markov chain, or
- run several shorter Markov chains?

Convergence Diagnostic

With a fixed cpu-time should we:

- use all time in one long Markov chain, or
- run several shorter Markov chains?
- One long chain:
 - ▶ only one burn-in period to discard
 - ▶ more likely that you really have converged
- Several shorter runs:
 - ▶ easier to evaluate convergence
 - ▶ easier to estimate the variance of the estimator (the chains are independent)

In practice one often use a combination of the two strategies

Variance of the MCMC estimator

Recall: We want to estimate $\mu = \int g(x)\pi(x) dx$ with

$\hat{\mu} = \frac{1}{n} \sum g(x_i)$ where $x_i \sim \pi(x)$.

In standard MC we have

$$x_1, x_2, \dots, x_n \sim \pi(x), \text{ i.i.d.}$$

This gives

$$E(\hat{\mu}) = \mu \text{ and } \text{Var}(\hat{\mu}) = \frac{\text{Var}(g(X))}{n}$$

We can estimate the variance $\text{Var}(\hat{\mu})$ as

$$\widehat{\text{Var}(\hat{\mu})} = \frac{\widehat{\text{Var}(g(X))}}{n}$$
$$\widehat{\text{Var}(g(X))} = \frac{1}{n-1} \sum (g(x_i) - \hat{\mu})^2$$

MCMC gives dependence samples, what is the variance then??

Autocorrelation

To **examine dependencies of successive MCMC samples**, the autocorrelation function can be used. Let x_1, \dots, x_N , where N denotes the number of samples, denote our MCMC chain.

The lag k autocorrelation $\rho(k)$ is the correlation between every draw and its k -th lag. For **N reasonably large**

$$\rho(k) \approx \frac{\sum_{i=1}^{N-k} (x_i - \bar{x})(x_{i+k} - \bar{x})}{\sum_{i=1}^N (x_i - \bar{x})^2},$$

where $\bar{x} = \frac{1}{N} \sum_{i=1}^N x_i$ is the overall mean.

- With increasing lag k we expect lower autocorrelations.
- If autocorrelation is still relatively high for higher values of k , this indicates high degree of correlation between our draws and **slow mixing**.

Example: Korsbetningen

Autocorrelation function for N (after discarding the burn-in period)

Effective sample size

A useful measure to compare the performance of different MCMC samplers is the **effective sample size (ESS)** Kass et al. (1998) *American Statistician* 52, 93–100..

- The ESS is the estimated number of independent samples needed to obtain a parameter estimate with the same precision as the MCMC estimate based on N dependent samples.

$$\text{ESS} = \frac{N}{\tau}, \quad \tau = 1 + 2 \cdot \sum_{k=1}^{\infty} \rho(k),$$

where τ is the autocorrelation time and $\rho(k)$ the autocorrelation at lag k .

Estimate of ESS

$$\text{ESS} = \frac{N}{\tau}, \quad \tau = 1 + 2 \cdot \sum_{k=1}^{\infty} \rho(k),$$

Estimate τ as

$$\tau = 1 + 2 \cdot \sum_{k=1}^m \hat{\rho}(k)$$

where $\hat{\rho}(k)$ is the sample autocorrelation function at lag k , and m is chosen to fulfill some criteria.

Different criteria exists.

Example: Korsbetningen - Effective sample size (ESS)

```
> library(coda)
> nsamples

[1] 8000

> ## single site
> effectiveSize(as.mcmc(res1))

      N      theta
20.28367 16.30797

> ## block update
> effectiveSize(as.mcmc(res2))

      N      theta
506.6220 845.4659
```

>
The precision of the MCMC estimate of the posterior mean of N based on 8000 samples from a single site update is as good as taking 16 independent samples!

Geweke diagnostics

The MCMC chain is divided into two windows

- the first $x\%$, and
- the last $y\%$ of the iterates

(coda default: $x = 10$, $y = 50$). For both windows the mean is calculated.

If the chain is stationary both values should be equal and Geweke's test statistic (z-score) follows an asymptotical standard normal distribution.

Example: Korsbetningen - Geweke plot
